ABSTRACT: The Hematopoietic stem cell transplantation (HSCT) is used in children as a definitive treatment for various oncological, immune deficiencies, hemoglobinopathy, and malignancies diseases that involve the hematological system, congenital metabolism disorders, among others. To characterize the clinical and epidemiological profile of children and adolescents submitted to HSCT at a referral service in the state of Rio Grande do Norte. This is a quantitative, retrospective, observational, descriptive and analytical quantitative approach approaching the medical records of children and adolescents submitted to HSCT in a referral hospital service for this type of transplantation in the state of Rio Grande do Sul North (RN). The final sample consisted of 35 records patients aged between 2 and 18 years old who underwent HSCT from February 2008 to December 2015 and who presented the data necessary for the study. The records analyzed showed a little majority of male patients (51.42%) and 60.00% of these men were students and 71.42% lived in the state of the Rio Grande do Norte. According to the clinical characteristics, 34.3% of the patients had Acute Lymphoblastic Leukemia and 25.71% had Acute Myeloid Leukemia as the main diagnosis. Gastrointestinal toxicities were the most frequent (97.1%) and all patients received antineoplastic/chemotherapeutic and antiemetic treatment. The allogeneic HSCT was the most frequently performed (57.14%) and the most used source of Hematopoietic progenitor cells (HPC) was the peripheral blood (54.29%) and 5.71% of these patients developed the Graft versus Host Disease (GVHD), of which one was affected by acute GVHD and another by chronic GVHD. Sepsis was the most frequent cause of death (60%). The profile of the clinical variables presented by the children and adolescents of this study shows that the most prevalent diagnosis was ALL, the most frequent toxicities were gastrointestinal, cardiac, respiratory and hematological, the most common HSCT was allogeneic peripheral blood and the greatest cause of mortality was sepsis. These data are similar to studies conducted in North America, Europe and Asia.

KEYWORDS: Hematopoietic Stem Cell Transplantation. Bone Marrow Transplantation. Child. Adolescent. Epidemiology.

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) is used in children as a definitive treatment for different oncological, immune deficiencies, hemoglobinopathies, and diseases malignancies that involve the hematological system, congenital metabolism disorders, among others. HSCT consists

of a treatment option for some of these diseases or even the only option for others that probably have not responded to other therapeutic modalities, with an increase in survival after transplantation, contributing to its use (YEŞİLİPEK, 2014).

Although these diseases are indicated for HSCT, there are still some factors that need to be considered such as the underlying disease, the

clinical conditions of the patient, the existence of a compatible donor, adequate infrastructure for performing the procedure, specialized multi-professional and trained team, after using other treatment possibilities. Also, the family, psychological and socioeconomic conditions should be considered for continuity of home care after hospital discharge (BRASIL, 2008).

HSCT is a procedure in which hematopoietic stem cells (HTCs) are intravenously infused to restore normal functional bone marrow (BM). To obtain favorable conditions of multiplication for these stem cells and also to cause immunosuppression, in the stage before the transplant, the conditioning is performed, being a stage with high doses of chemotherapy are administered. HSCT is indicated when BM is affected or when hematopoietic toxicity is a limiting factor for the aggressive treatment of the disease (GLUCKMAN, 2012; NORKIN; WINGARD, 2017).

The HSCT is classified according to the donor in autogenic when the patient's cells are collected and cryopreserved for subsequent infusion; syngeneic when collected from homozygous twin; and the allogeneic for which the source of the cells will be a compatible donor that may or may not be related (AZEVEDO et al., 2017a; DANBY; PROTHEROE; ROBERTS, 2017).

Due to advances in supportive care, HSCT is currently a therapeutic modality with significant degrees of success against some diseases that would probably be lethal or would not have definitive cure, such as Sickle Cell Anemia and Aplastic Anemia (FIGUEIREDO; KERBAUY; LOURENÇO, 2011; NASH; GADI, 2011; YEŞILPEK, 2014). For some patients, treatment with HSCT shows a significant improvement in overall survival (AZEVEDO et al., 2017b; KLUSMANN et al., 2012).

Although HSCT is considered a viable treatment option, it still has some significant limitations (BOUCHER et al., 2015). Its disadvantages are the acute complications resulting from the conditioning period that occurs within the first 100 days after its completion, which may affect several organs and systems and be more severe in the period of medullary aplasia, lasting around 15 to 28 days (BRASIL, 2008). Also, late effects of the transplantation process such as endocrine, metabolic, renal, ophthalmologic and neurocognitive diseases, sequels such as cardiomyopathies, liver dysfunction or cirrhosis, need for hormone replacement, acute or chronic graft versus host disease (GVHD) skeletal and cardiac disorders are also reported. However, solid

tumors are considered rare (KLUSMANN et al., 2012; LEVY et al., 2012).

In a retrospective study with 40 children carried out in Uruguay, the most common diagnoses among hematologic malignancies, there were ALL (n = 15) and AML (n = 13). These data are similar to those found in this study. All children were also submitted to HSCT (DUFORT et al., 2016). There are few studies on hematopoietic stem cell transplantation in the Brazilian pediatric population. Thus, it is a procedure that still requires research in the area, which highlights the importance of knowing the clinical and epidemiological profile of children and adolescents submitted to this procedure.

Thus, this study aimed to characterize the clinical and epidemiological profile of children and adolescents submitted to HSCT in a referral service in the state of Rio Grande do Norte, located in the northeast region of Brazil.

MATERIAL AND METHODS

This is an epidemiological, quantitative, retrospective, observational, descriptive and analytical study. The medical records of children and adolescents submitted to HSCT were analyzed in a reference hospital service for this type of procedure in the state of Rio Grande do Norte.

Data were collected between March and September of 2016 by secondary data. The sources were all medical records of patients aged between two and 18 years old who performed the HSCT in the service from February 2008 until December of 2015, characterizing the cohort follow-up time. For the purposes of this study, the subject with up to 12 years old will be considered as a child, and adolescents will be those between 12 and 18, according to the Statute of the Child and Adolescent (BRASIL, 1990). Also, HSCT is considered as the outcome for this study.

The study population was composed of all the patients who performed the HSCT in the service studied. The sample was a census type, considering all the existing population, in a total of 35 medical records of children and adolescents attended during the period, with medical indication for performing the HSCT, regardless of the modality of transplantation performed, that met the inclusion and established criteria. The records of patients aged between zero and 18 years old, of both genders, who underwent autologous and allogeneic transplant procedures were included. Two medical records that did not present information capable of providing the

data necessary for the study due to incompleteness were excluded.

The data collection in the medical records occurred through the completion of a structured instrument, specifically designed for this study, which addressed sociodemographic and clinical variables. The collection of data was performed with the Medical Archive and Statistics Service through prior schedules. The sociodemographic variables were date and place of birth, place of residence, age, gender, race, educational level, family and per capita income, marital status, type of residence, housing characterization, and occupation. Regarding the clinical variables, the following were considered: current situation with the HSCT service, time between the date of diagnosis and the HSCT, time of follow-up by the transplant service, diagnosis that indicated HSCT, main diagnostic tests, type of HSCT performed, presence of toxicities, established treatments, presence of acute or chronic GVHD, causes of death, and transplant survival.

After collected, the data were entered in a Microsoft Excel® 2010 spreadsheet, tabulated and organized into tables with absolute and relative

frequencies by gender, age, race, marital status, education level, place of residence, diagnoses, toxicities, treatments used, HSCT types, Hematopoietic progenitor cells types (HPC), allogeneic transplant donor, GVHD, causes of death and total.

The protocol of this research was approved by the Research Ethics Committee of the Federal University of Rio Grande do Norte (UFRN) on July 1, 2015, under the opinion of number 1,132,720, CAAE number 46202715.7.0000.5537, according to the precepts established in Resolution 466/12 of the National Health Council. It was also requested a Letter of Consent and a Term of Concession for the institution where the research was carried out and obeyed the fundamental principles of bioethics.

RESULTS AND DISCUSSION

There were 18 male of the 35 patients included in the study (51.42%), aged between two and 18 years old and with a mean age of 10.91 years old. Among the medical records, 77.16% did not present information about their race, 60.00% were students and 71.42% resided in the RN (Table 1).

Table 1. Sociodemographic characteristics of children and adolescents submitted to HSCT in the state of Rio Grande do Norte between 2008 and 2015. Natal/RN, 2017 (n=35).

Variables	n	%
Gender		
Male	18	51.42
Female	17	48.58
Age group

Total	35	100.00

The distribution of patients according to gender did not present a statistically significant difference, with 51.42% of the male patients. A 17-year follow-up study in institutions in the Brazilian states of Paraná and São Paulo, with patients younger than 19 years old submitted to HSCT had a greater number of males, of whom 74 were females and 137 were male (MORANDO et al., 2010).

Regarding their race, only 22.84% of the medical records presented this information. Underreporting is a situation commonly found in health information systems. It is important that all necessary patient information is recorded not only for research purposes but for the patient, also for consultation by medical, administrative and legal professionals. Therefore, in this case, it was not possible to compare these data with other studies, although underreporting of the breed has been

commonly found in several studies (SOUZA et al., 2017).

The main diagnoses were Acute Lymphoblastic Leukemia (ALL) with 34.3% of cases and Acute Myeloid Leukemia (AML) with 25.71%, respectively. Gastrointestinal toxicities occurred in 97.1% of the cases and 100% of the subjects received antineoplastic/chemotherapeutic and antiemetic treatment.

According to the types of HSCT performed, 57.14% were submitted to allogeneic transplantation, the most used source of HPC was Peripheral blood (PB) (54.29%), only 8.56% were retransplanted and 5.71% developed GVHD, one affected by acute GVHD and another affected by a chronic form. Sepsis developed 60% of deaths (Table 2).

* Multiple choice.

The diagnosis of the base disease for most frequent HSCT was ALL (34.3%), followed by AML (25.71%). A study with children younger than 3 years old demonstrated similar results when the most common diagnoses were ALL (66.7%) and AML (26.7%) (LEVY et al., 2012). Another study carried out with children and adolescents with leukemia showed a higher prevalence for ALL (199) on AML (89) (MORANDO et al., 2010). ALL is the most common type of cancer found in children (INSTITUTO NACIONAL DO CÂNCER JOSÉ ALENCAR GOMES DA SILVA, 2017).

HSCT shows a strong focus on the clinical cure process, with the use of intensive therapy with high risk of treatment-related toxicity and unpredictable complications. The main toxicities found in the subjects of this study were gastrointestinal (97.1%), followed by cardiovascular (62.85%), respiratory (62.85%) and hematologic (60%) (SANTOS, 2015). The toxicities have a great relationship with the complications related to the conditioning period (FIGUEIREDO; KERBAUY; LOURENÇO, 2011), as well as the gastrointestinal toxicities are risk factors for the infection, so it is necessary to invest in techniques for its prevention (SRINIVASAN et al., 2014).

To perform a HSCT, the patient undergoes the conditioning process, which aims to generate immunosuppression to prevent the donor cells from being rejected by the recipient. This process occurs through irradiation and/or chemotherapy, so all patients in this study underwent anti-neoplastic/chemotherapeutic treatment (GRATWOHL; CARRERAS, 2013; JURIC et al., 2016).

High doses of radiotherapy and/or chemotherapy used in conditioning can affect all of the patient's organs and lead to side effects. The development of complications may be related to predisposition, immunosuppressive therapies and toxicities related to pre-transplant therapies and presence of other factors during the conditioning regimen (HABIBI et al., 2016).

The use of antibiotics may be indicated as prophylactic therapy, because in the months after transplantation, the occurrence of infections due to immunosuppression caused by the conditioning and the treatment used to avoid GVHD is common. Therefore, a wide range of prophylactic drugs is

used (FIGUEIREDO; KERBAUY; LOURENÇO, 2011). With the establishment of antiviral and antifungal prophylaxis after the 2000s, there was a significant reduction in the incidence and characteristics of infections in these patients (SRINIVASAN et al., 2014).

Infection complications are among the main causes of transplant-related morbidity and mortality (MAJHAIL et al., 2012; YEŞİLİPEK, 2014). In this study, the use of antibiotics occurred in 97.14% of the subjects studied, which demonstrates the concern with the cases of infection of patients transplanted with HTCs.

Antiemetics are used in all patients as a consequence of the administration of antineoplastic/chemotherapeutic agents, as the case with the studied individuals, since the main side effects of alkylating drugs are nausea and emesis (SANTOS, 2015). Gastrointestinal complications are responsible for a significant part of the morbidity and mortality due to dehydration, malnutrition and hydroelectrolytic imbalance (TUNCER et al., 2017) and, they can be fatal and require special attention when they occur in children and adolescents.

The anti-neoplastic treatment may also cause hematological toxicity, reducing the cell lines of the blood and leading the patients to myelosuppression, with leukopenia, thrombocytopenic/thrombocytopenic progression, anemia or medullary depression (POZER et al., 2012). Hematopoietic tissue is more vulnerable to cytotoxic drugs, since chemotherapeutics are toxic to rapidly proliferating tissues, characterized by high mitotic index and a short cell cycle (SANTOS, 2015).

Cardiovascular complications associated with cardiotoxicity are adverse events that can occur acutely or chronically, with significant morbidity and mortality for children and young adults, and they may also lead to heart failure, arterial hypertension, metabolic syndromes, thromboembolism, pericarditis, arrhythmias or ischemia (ROTZ et al., 2017).

Pulmonary complications affect about 40% to 60% of CPH transplants and are considered important causes of morbidity and mortality. According to some studies, pulmonary toxicity is responsible for 50% of deaths IN transplanted

patients, and patients with pulmonary complications are more likely to die than those who do not present these complications (BRODOEFEL et al., 2013; PEÑA et al., 2014).

Although the first allogeneic HSCT was performed in 1957 by the Nobel laureate E. Donnall Thomas (HENIG; ZUCKERMAN, 2014), studies have shown a reduction in cases of autologous transplants only after the 2000s. A study with 65 patients undergoing autologous HSCT found 92% of autologous transplants from 1990-1999 compared to 8% performed between 2000 and 2009 (SRINIVASAN et al., 2014).

In this study, autologous transplantation was performed in only three patients. The other 32 underwent allogeneic transplantation. A study carried out in the United States of America with medical records of patients who died after the procedure found similar results, when 69% of the transplants were allogenic, 18% autogenic and 13% through Umbilical Cord and Placental Blood (UCPB) (ULLRICH et al., 2016). The results of autologous transplants are superior due to the complications most common to allogeneic transplants. However, allogeneic transplants have a long-term gain because they present a lower frequency of relapse, which may justify the choice of the source of cells for transplantation (FIGUEIREDO; KERBAUY; LOURENÇO, 2011). Another reason for a predominance of allogeneic transplants is due to the fact that some diseases related to immune deficiencies have allogeneic transplantation as the only therapeutic option for cure (YEŞİLİPEK, 2014).

PB was the source of progenitor cells predominantly employed in HSCT (54.29%) of the patients of this study, differently from the literature, where the bone marrow is highlighted as a source of material for the graft (MORANDO et al., 2010). In this study, BM was the second largest source (31.42%), while umbilical cord blood (8.58%) was the least used source, although it is sources with

satisfactory results, many difficulties still exist for its wide use.

From the 2000s, there was a preference for other cellular sources other than the bone marrow (SRINIVASAN et al., 2014). Although survival rates are similar between the use of PB and BM cells, graft success is achieved in the case of PB more rapidly than bone marrow transplantation (MEISEL; KLINGEBERL, DILOO, 2013).

The prevalence of chronic GVHD in patients undergoing HSCT is about 40% to 60% and is the main cause of late mortality, mainly associated with infections (FIGUEIREDO; KERBAUY; LOURENÇO, 2011). Although it has decreased with new methods of conditioning and with and a lower risk in pediatric patients compared to adults, this frequency has increased especially by the use of allogeneic and unrelated transplants (YEŞİLİPEK, 2014).

In this case, the patients in this study had 5.81% rate of GVHD, even when related to a number of 19 grafts from SP, which presents a higher incidence of this complication (SHAW et al., 2009). A study conducted in this same service with pediatric and adult patients presented a small rate of occurrence of GVHD (4.04%) and a high HSCT rate of PB cells (77.94%; $p < 0.400$) (AZEVEDO et al., 2018) that confirms there was no relation between the occurrence of GVHD and the cellular source from PB. Although the two cases of GVHD caught the attention, the number of manifestations occurred within the expected incidence. The expected frequency of acute GVHD was reported between 30 and 50% of the cases of children undergoing HSCT (YEŞİLİPEK, 2014).

Of the five patients who died, all were adolescents, and 80% were male. Only one of the deaths occurred within the first seven months of treatment. Among the five deaths, three had diagnosis of ALL, one of AML and another of Aplastic Anemia (Table 3).

Table 3. Characterization of the deaths of children and adolescents submitted to HSCT in the state of Rio Grande do Norte between 2008 and 2015. Natal/RN, 2017 (n=5).

Variables	n	%
Gender		
Male	04	80.00
Female	01	20.00
Age group		
12 to 18 years old	05	100.00
Follow up time		
Up to 7 months	01	20.00
More than 7 months	04	80.00

Main Diagnosis		
Acute Lymphoblastic Leukemia	03	60.00
Acute Myeloid Leukemia	01	20.00
Anemia, Aplastic	01	20.00
Total	05	100.00

This study corroborates most of the studies, when infections are an important cause of mortality in children and adolescents treated with allogeneic HCTs, with a high incidence of infections in this group of patients (ZAUCHA-PRAZMO et al., 2017; PASQUINI; ZHU, 2014). In a contradictory way, a study carried out in the USA presented a rate of 59.18% of the deaths related to treatment toxicity and the others related to recurrence of the disease. An important finding in this study is that although a 91.42% rate of allogeneic transplants, which is related to a greater number of infections, the mortality rate was 14.28%, which may be considered low (STYCZYNSKI et al., 2016).

Progress in the treatment of childhood and adolescent cancer in the last four decades has been extremely significant. Changes in treatment and prophylaxis have helped in this progress (SRINIVASAN et al., 2014). With this advancement, about 80% of children and adolescents affected by cancer can be cured if diagnosed early and treated in specialized centers (BRASIL, 2008), although childhood survivors of HSCT have a risk for dysfunction in all systems, as well as secondary tumors (LEVY et al., 2012).

One limitation of this study is that it deals with research performed with secondary data, from medical records that could be incomplete. However, in cases where it was not possible to collect the necessary information directly related to the object being studied, the medical records were excluded from the analyzed sample as a way to control this information bias. Also, the unicentric approach and sample size considered small for epidemiological studies are limiting factors for the external validity of the study.

This study constitutes an important starting point for the clinical and epidemiological analysis of children and adolescents submitted to HSCT, which still deals with a procedure that requires expanded studies in Brazil and in the world, mainly because it is the highlighted population. There are few studies that show the epidemiological data of children and

adolescents transplanted in Brazil, with specific surveys, without a national survey to establish the profile of this national patients. Besides to promoting a discussion on the subject treated, the research incites the opportunity to know the profiles of patients assisted in the services of HSCT that can help in the understanding and the choice of better therapeutic options.

The profile of the clinical variables of the children and adolescents in this study showed that ALL was the most prevalent diagnosis, gastrointestinal, cardiac, respiratory and hematological were the most frequent toxicities, allogeneic peripheral blood was the most performed HSCT and sepsis was the major cause of mortality. These data are similar to data found in North America, Europe and Asia, except for the use of peripheral blood HPC when research in Europe, Asia, and the United States already demonstrated a significant number of cord blood and placental procedures.

Additional studies with a larger number of patients and in other reference services in Brazil are necessary to link the aspects described in the results and show the Brazilian reality to contribute to the advancement in health research. Although there are few distinctions, this study allowed concluding that the epidemiological characteristics of the patients of a Brazilian service do not differ from those performed with populations of international studies.

RESUMO: O Transplante de Células-Tronco Hematopoéticas (TCTH) é utilizado em crianças como um tratamento definitivo para várias doenças oncológicas, imunodeficiências, hemoglobinopatias, malignidades que envolvem o sistema hematológico, distúrbios de metabolismo congênito, entre outros. Caracterizar o perfil clínico e epidemiológico de crianças e adolescentes submetidos ao TCTH em um serviço de referência do

estado do Rio Grande do Norte. Trata de um estudo epidemiológico de abordagem quantitativa, do tipo coorte retrospectiva, observacional, descritivo e analítico onde foram abordados os prontuários de crianças e adolescentes submetidos ao TCTH em um serviço hospitalar de referência para esse tipo de transplante no estado do Rio Grande do Norte (RN). A amostra final foi composta por 35 prontuários de pacientes com idade entre dois e 18 anos que realizaram o TCTH no período de fevereiro de 2008 a dezembro de 2015 e que apresentavam os dados necessários ao estudo. Do total de prontuários analisados houve discreta maioria de pacientes do sexo masculino (51,42%). Destes, 60,00% eram estudantes e 71,42% residiam no estado do RN. De acordo com as características clínicas, 34,3% apresentaram como diagnóstico principal a Leucemia Linfoblástica Aguda e 25,71% a Leucemia Mieloide Aguda. As toxicidades gastrointestinais foram as que mais ocorreram (97,1%) e todos receberam tratamento com antineoplásicos/quimioterápicos e antieméticos. O TCTH alogênico foi o mais frequentemente realizado (57,14%) e a fonte de CPH mais utilizada foi o sangue periférico (54,29%) e 5,71% desenvolveram a Doença do Enxerto Contra Hospedeiro (DECH), dos quais um foi acometido por DECH aguda e outro pela forma crônica. A causa de morte com maior frequência foi a sepse (60%). O perfil das variáveis clínicas apresentadas pelas crianças e adolescentes desta pesquisa mostram que o diagnóstico mais prevalente foi o de LLA, as toxicidades que mais ocorreram foram as gastrointestinais, cardíacas, respiratórias e hematológicas, o TCTH mais realizado foi o alogênico de sangue periférico e a maior causa de mortalidade foi a sepse. Tais dados se assemelham aos estudos realizados na América do Norte, Europa e Ásia.
